Elevated concentrations of atmospheric carbon dioxide (CO<sub>2</sub>), a consequence of anthropogenic global change, may profoundly interfere with tritrophic interactions. Such effects have rarely been investigated. We used the system composed of Brassica plants, the cabbage aphid *Brevicoryne brassicae* and the endoparasitoid *Diaeretiella rapae* to compare effects of elevated CO<sub>2</sub> (800 ppm) versus ambient CO<sub>2</sub> (400 ppm). Plants were exposed to the CO<sub>2</sub> concentrations for up to 10 weeks, aphids for 2-3 generations, and parasitoids for 1 generation. Concomitant bioassays with herbivore-infested plants exposed to parasitoids were also conducted. A significantly lower proportion of aphids were parasitized under elevated compared to ambient CO<sub>2</sub>. Parasitoid progeny emerged earlier but offspring adults were shorter lived under elevated CO<sub>2</sub>. Plant glucosinolate concentrations were higher under elevated compared to ambient CO<sub>2</sub>. However, contrary to expectations, aphid glucosinolate concentrations were significantly lower under elevated CO<sub>2</sub>. Likewise aphid body mass remained approximately 20% lower under elevated compared to ambient CO<sub>2</sub>. Thus, elevated CO<sub>2</sub> seems to have enhanced plant direct defense through an increase in natural plant defense compounds, but also led to a reduction in indirect defense through decreased parasitism and parasitoid longevity. Our results indicate, for the first time, a conflict between bottom-up and top-down control under elevated CO<sub>2</sub>.
